## Editorial Scope

### Topics

Foundations and Trends<sup>®</sup> in Theoretical Computer Science publishes survey and tutorial articles in the following topics:

- Algorithmic game theory
- Computational algebra
- Computational aspects of combinatorics and graph theory
- Computational aspects of communication
- Computational biology
- Computational complexity
- Computational geometry
- Computational learning
- Computational Models and Complexity
- Computational Number Theory
- Cryptography and information security
- Data structures
- Database theory
- Design and analysis of algorithms
- Distributed computing
- Information retrieval
- Operations Research
- Parallel algorithms
- Quantum Computation
- Randomness in Computation

### Information for Librarians

## ABSTRACT

Fourier analysis has been extremely useful in many areas of mathematics. In the last several decades, it has been used extensively in theoretical computer science. Higher-order Fourier analysis is an extension of the classical Fourier analysis, where one allows to generalize the “linear phases” to higher degree polynomials. It has emerged from the seminal proof of Gowers of Szemerédi’s theorem with improved quantitative bounds, and has been developed since, chiefly by the number theory community. In parallel, it has found applications also in theoretical computer science, mostly in algebraic property testing, coding theory and complexity theory.

The purpose of this book is to lay the foundations of higher-order Fourier analysis, aimed towards applications in theoretical computer science with a focus on algebraic property testing.

## Introduction

---

The purpose of this text is to provide an introduction to the field of higher-order Fourier analysis with an emphasis on its applications to theoretical computer science. Higher-order Fourier analysis is an extension of the classical Fourier analysis. It was initiated by a seminal paper of Gowers [37] on a new proof for Szemerédi’s theorem, and has been developed by several mathematicians over the past few decades in order to study problems in an area of mathematics called additive combinatorics, which is primarily concerned with linear patterns such as arithmetic progressions in subsets of integers. While most of the developments in additive combinatorics were focused on the group  $\mathbb{Z}$ , it was quickly noticed that the analogous questions and results for the group  $\mathbb{F}_2^n$  are of great importance to theoretical computer scientists as they are related to basic concepts in areas such as property testing and coding theory.

Classical Fourier analysis is a powerful tool that studies functions by expanding them in terms of the Fourier characters, which are “linear phase functions” such as  $n \mapsto e^{-\frac{2\pi i}{N}n}$  for the group  $\mathbb{Z}_N$ , or  $(x_1, \dots, x_n) \mapsto (-1)^{\sum a_j x_j}$  for the group  $\mathbb{F}_2^n$ . Note that  $n$  and  $\sum a_j x_j$  are both linear functions. Fourier analysis has been extremely successful in the study

of certain linear patterns such as three-term arithmetic progressions. For example, if the number of three-term arithmetic progressions in a subset  $A \subseteq \mathbb{Z}_N$  deviates from the expected number of them in a random subset of  $\mathbb{Z}_N$  with the same cardinality as  $A$ , then  $A$  must have significant correlation with a linear phase function. In other words, the characteristic function of  $A$  must have a large non-principal Fourier coefficient. Roth [66] used these ideas to show that every subset of integers of positive upper density contains an arithmetic progression of length 3. However, classical Fourier analysis seems to be inadequate in detecting more complex linear patterns such as four-term or longer arithmetic progressions. Indeed, one can easily construct dense sets  $A \subseteq \mathbb{Z}_N$  that do not have significant correlation with any linear phase function, and nevertheless do not contain the number of four-term arithmetic progressions that one expects by considering random subsets of the same cardinality. Hence in order to generalize Roth's theorem to arithmetic progressions of arbitrary length, Szemerédi [76, 77] departed from the Fourier analytic approach and appealed to purely combinatorial ideas. However, his proof of this major result, originally conjectured by Erdős and Turán [27], provided poor quantitative bounds on the minimal density that guarantees the existence of the arithmetic progressions of the desired length. Later Furstenberg [31] developed an ergodic-theoretic framework and gave a new proof for Szemerédi's theorem, but his proof was still qualitative. His theory is further developed by - to name a few - Host, Kra, Ziegler, Bergelson, Tao (See e.g. [51], [88], and [10, 82]), and there are important parallels between this theory and higher-order Fourier analysis. Indeed some of the terms that are commonly used in higher-order Fourier analysis such as "phase functions" or "factors" are ergodic theoretic terms.

Generalizing Roth's original proof and obtaining good quantitative bounds for Szemerédi's theorem remained a challenge until finally Gowers [37] discovered that the essential idea to overcome the obstacles described above is to consider higher-order phase functions. His proof laid the foundation for the area of higher-order Fourier analysis, where one studies a function by approximating it by a linear combination of few higher-order phase functions. Although the idea of using higher-order phase functions already appears in Gowers's work [37], it was not

until more than fifteen years later that some of the major technical difficulties in achieving a satisfactory theory of higher-order Fourier analysis have been resolved. By now, due to great contributions by prominent mathematicians such as Gowers, Green, Tao, Szegedy, Host, Kra and Ziegler (See [75] and [80] and the references there), there is a deep understanding of qualitative aspects of this theory. However, despite these major breakthroughs, still very little is known from a quantitative perspective as many of the proofs are based on soft analytic techniques, and obtaining efficient bounds is one of the major challenges in this area.

This survey will emphasize the applications of the theory of higher-order Fourier analysis to theoretical computer science, and to this end, we will present the foundations of this theory through such applications, in particular to the area of property testing. In the early nineties, it was noticed by Blum *et al.* [20] and Babai *et al.* [6] that Fourier analysis can be used to design a very efficient algorithm that distinguishes linear functions  $f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2$  from functions that are far from being linear. This initiated the area of property testing, the study of algorithms that query their input a very small number of times and with high probability decide correctly whether their input satisfies a given property or is “far” from satisfying that property. It was soon noticed that generalizing the linearity test of Blum *et al.* [20] and Babai *et al.* [6] to other properties such as the property of being a quadratic polynomial requires overcoming the same obstacles that one faces in an attempt to generalize Fourier analytic study of three-term arithmetic progressions to four-term arithmetic progressions. Hence in parallel to additive combinatorics, theoretical computer scientists have also been working on developing tools in higher-order Fourier analysis to tackle such problems. In fact some of the most basic results, such as the inverse theorem for the Gowers  $U^3$  norm for the group  $\mathbb{F}_2^n$ , were first proved by Samorodnitsky [70] in the context of property testing for quadratic polynomials.

In [Part I](#) we discuss the linearity test due to Blum *et al.* [20] and its generalization to higher degree polynomials. We will see how this naturally necessitates the development of a theory of higher-order Fourier analysis. In [Part II](#) we present the fundamental results of the theory of higher-order Fourier analysis. Since we are interested in the

applications to theoretical computer science, we will only consider the group  $\mathbb{F}_p^n$  where  $p$  is a fixed prime, and asymptotics are as  $n$  tends to infinity. Higher-order Fourier analysis for the group  $\mathbb{Z}_N$ , which is of more interest for number theoretic applications, shares the same basic ideas but differs on some technical aspects. For this group, the higher order phase functions, rather than being exponentials of polynomials, are the so called nilsequences. We refer the interested reader to Tao [80] for more details. In [Part III](#) we use the tools developed in [Part II](#) to prove some general results about property testing for algebraic properties.

Throughout most of the text, we will consider fields of constant prime order, namely  $\mathbb{F} = \mathbb{F}_p$  where  $p$  is a constant, and study functions from  $\mathbb{F}_p^n$  to  $\mathbb{R}$ ,  $\mathbb{C}$ , or  $\mathbb{F}_p$  when  $n$  is growing. Our choice is mainly for simplicity of exposition, as there have been recent research that extend several of the tools from higher-order Fourier analysis to large or non-prime fields. We refer the interested reader to a paper by Bhattacharyya *et al.* [12] for treatment of non-prime fields. In [Chapter 8](#) we will discuss a paper by Bhowmick and Lovett [19] considering the case  $\mathbb{F}_p^n$  when  $p$  is allowed to grow as a function of  $n$ .
